ABSTRACT

Simeulue Island, off the west coast of northern Sumatra, straddles the boundary of the 2004 and 2005 Sunda megathrust ruptures. The 2004 and 2005 earthquakes nucleated northwest and southeast of Simeulue, respectively, and each ruptured bi-laterally toward the 100-km-long island. Cumulative uplift was 1.5 m at both the northwest and southeast tips of the island but diminished toward the island’s center, where uplift was 0.3 m or less. Hence, although the 2004 and 2005 uplifts overlapped, there was an uplift deficit, or saddle, on central Simeulue.

In addition to enabling observations of coseismic uplift, Pentecos coral microatolls enable measurements of postseismic and interseismic elevation changes. Whereas uplift in the year after May 2005 was negligible (< 10 cm) at the northwest and southeast ends of Simeulue, 30 cm of postseismic uplift occurred during that period in central Simeulue. Moreover, analysis of microatoll morphology indicates that, averaged over decades and longer, interseismic strain accumulation rates are lower in central Simeulue than at the island’s ends.

Historical intensity data imply that prior to 2005 the last great earthquake caused by rupture of the megathrust under Nias island, to the south, occurred in A.D. 1843; initial 12-hour dates from uplifted fossil microatolls suggest that, like the 2005 rupture, the 1843 rupture extended north to southern Simeulue. Additional preliminary U-Th dates from uplifted fossil microatolls suggest that earlier earthquakes, in A.D. 1843 and some time around A.D. 1799, also involved rupture of Nias and southern Simeulue. Thus it appears that the ~1799, 1843, 1861 and 2005 ruptures were similar in that they extended into but not through the Simeulue Saddle. However, at sites in southeastern Simeulue, uplifts in ~1799 and in 1843 were much smaller than in 2005, and the ~1799, 1843, and 1861 events may be regarded as a tripartite.

North of the Simeulue Saddle, the most recent event apparently occurred around A.D. 1440, and it may have been preceded by one or two other earthquakes in close succession (analysis is still very preliminary). Altogether, these observations suggest that the Simeulue Saddle is a poorly coupled segment of the megathrust that serves as a persistent barrier to rupture.

Fossil Microatoll deaths in A.D. ~1799
Fossil Microatoll deaths in A.D. ~1980
Fossil Microatoll deaths in A.D. ~1440
Fossil Microatoll deaths in A.D. ~1327
Fossil Microatoll deaths in A.D. ~1390
Fossil Microatoll deaths in A.D. ~1843
